Abstract

The purpose of this study is to determine if various measures developed from financial analysts forecasts of earnings for firest can be exploited in predicting future bankruptcy. The analysis consists of two major parts.

In the first part, four properties of analysts forecasts are discussed and investigated: forecast level, forecast dispersion. forecast error, and forecast bias. Tests are conducted to determine if there are systematic differences in the four properties for failing firms as compared to healthy firms in years prior to the bankraptcy of the failing firms. Several statistically significant differences are apparent. Failing firms tend to be associated with lower forecasted earnings, higher dispersion in learnings forecasts a moss multiple forecasters, greater error in forecasts, and own mounts in the forecasts. Differences between fixiling as now a firms in how the properties change, both within learns and are a significant and properties change. Both within learns and are a significant.

THE PROPERTY OF THE PROPERTY O

In the second part of the study, measures reflection, bus componenties, and how they change over time, are used to discuring outsing from healthy arms. Edit constants and multivariete model, are are attached to distribute a marve model, which case to all finds as healthy, in firtinguishing between groups. The constant is all contains as healthy, in firtinguishing between groups. The constant is and a cessure that bear product or especially are to examine the contains of the constant of the contains of the

correct classification of between 33% to 49% of firms that any incorrectly classified by the naive rule (depending on the year peron to bankruptcy). Combining various measures in a multivariate approach permits improved classification accuracy in particular situations. The general conclusion is that measures developed from forecasts of earnings do reflect conditions that are associated with future failure.

SOURCE DESCRIPTION OF THE PROPERTY OF THE PROP

AMALYSTS: EARMINGS FORECASTS: AN ALTERNATIVE DATA SOURCE FOR FAILURE PREDICTION

1.1 Introduction

Componate bankruptcy, failure or distress can result in considerable costs to management, investors, creditors, and customers. The prediction of componate failure ex ante can provide the time to react and minimize those costs. The most common source of information for assessing financial health and developing models to predict failure is componate accounting reports. Several past studies have assessed the ability of combinations of accounting ratios to predict bankruptcy. (See Zavgren [1983] for a review.)

There are, however, several weakness in the use of accounting data to predict corporate failure. Accounting data is produced only periodically, is historical rather than prospective, and reflects events that have primarily endogenous to the first. Accounting measures are sensitive to the choice of accounting procedures, subject to "window dressing", and inevitable vary is adjuicted across firms and industries as a function of the constant of operations and technology. In addition, because of intervallationships between measures, researchers have found that individual ratios are inconsistent predictors across tests and samples.

The shed, investigates the usefulness of another the order the production of constant failure, one involving the use forests fundanced analysts forests forests for a constant failure. The propose in the constant forms of the propose in the constant forms of the propose in the constant forms.

explosites to predict bankruptcy.

1.7 Background

THE PROPERTY OF THE PROPERTY O

Earnings are considered by investors and analysts to be a preferred expectational data item (Change and Most [1980]) and have the greatest information content of various accounting variables (Gonedes [1974]); thus there tends to be special importance attached to the information reflected in earnings. Various studies of financial analysts forecasts of earnings have been conducted (See Givoly and Lakonishok [1984] for review). Several qualities of FAF suggest their usefulness as an information source and their potential ability to aid in failure prediction. FAF tend to outperform mechanical models based on past historical earnings in predicting future learnings (Barefield and Comiskey [1975]; Sollins and Repwood [1980]; Fried and Givoly [1982]). This seperitrity is more pronounced in years where there is a turning point in the earnings thend (Barefield and Comiskey). FAF apparently is to t information not copiumed by historical trends in earnings officed and Brioly) and may inefter transide information (Model-Krein) in a Ajinkya [1982]). Analysts revise their forecasts in response to information contained in quarterly earnings announcements (Brown and Rozeff [1979]) but the trend of FAF is smoother than actia. tronis (TrichHield, Dyckhan and Estimishot E(9781), diges to m andlysts separate a permanent from a temporary compuner, in reported carnings numbers. Studies have indicated an accounting **FIG. and nowledge to FAF, with stuck prices (Nerderhoffer or). 8 3 3 5 5 7 27 5.501 5 60 L 160 500 E1979,198 1, Electric above

Exitation [1781]. Brown, Foster and Noreen [1985]). Securities trading strategies using FAF and revisions in FAF indicate that FAF have information content for the securities market (Givoly and Lakonishok [1980], Abdel-khalik and Ajinkya). Furthermore, FAC appear to be a more adequate surrogate for the securities market earnings expectations than are naive predictions based on historical earnings (Malkiel [1970], Malkiel and Cragg [1970], Fried and Givoly [1982]). Collectively these findings indicate that FAF are a useful, comprehensive piece of information which reflect information exogenous to firms' accounting systems.

Of particular interest in the context of bankruptcy presistion are measures of risk derived from FAF. The error in earnings forecasts has been shown analytically to be an appropriate indication of uncertainty (Sukierman and Givoly [1982]). The dispersion of forecasts across analysts and the unpredictability of earnings have been shown empirically to be associated with traditional risk measures such as beta and the standard deviation of returns (Givoly and Lastonishok [1983]). In addition the dispersion of Ferfice to the class to be superior to measures of beta, economy risk, informative class, and interest rate risk in explaining expected return (Mala et 1981)). In short, dispersion and unpredictability in FAF may salve as a vasful profession is a consequence measures measure value to empirical researchers because unlike most traditional and converses. These are "ed ante" measures of risk (Givol and 1999).

The residence of temporal to product the production and the few residuals and the

general relies on accounting data, which is historical, reflect, a of information primarily endogenous to the firm, subject confounding influences such as manipulation and the choice of accounting procedures, and provided only periodically. Financial analysts forecasts are prospective, reflective of a broad information set, and provided and revised in a timely manner. FAF can be expected to reflect macro-economic events, industry expectations and firm—specific non-accounting information (e.g. contracts, order back—logs, capital expenditures). Research has indicated that FOF and risk measures developed from FAF have useful information content.

1.3 Chiective

WWW. Chicks System Bessels bessels bessels broken

The objective of this study is to empirically investigate the potential usefulness of measures developed from financial analysts forecasts of exceings in predicting corporate bankruptcy. In gameral the approach used is to identify a sample of failed files and a matched sample of non-failed firms (Section 2), to crance easures of various procedures of analysts earnings for most or investigate if the measures differ systematically between failing and healthy firms (Section 3), and to test the ability of the measures to discriminate between the two groups of firms (Section 3).

Z. Data and Sample

2.1 The Data Rounce - IPES

The data is near for analyst communication occities as the

Institutional Brokers Estimate System (IBES) published by Lynco. Jones, and Ryan, a New York based brokerage firm. (An historical summary data tape covering each month from January 1975 through July 1985 was made available by Lynch, Jones, and Ryan.) Earnings forecast data for 4305 firms were available on the IDES tage. However, the period covered on the tape for individual firms ranged from one month to the maximum possible nine years, six months.

partishans forecasts up to two years prior to the announcement of the actual earnings number from multiple forecasters who report their predictions to the IBES service. Each month IBES provides information on the mean estimate, median estimate, high estimate, low estimate, standard deviation of estimates, number of coward revisions since the previous month, number of downward revisions, as well as various other data such as monthly stock price and edjustment factors related to stock splits.

2.2 Sample

Index were reviewed for the period January 1977 through September 1985 to develop a list of firms declaring bankruptcy. The list was cross-referenced with firms on the IBES data tape. IBES contained data for 98 bankruph firms, but 50 firms were drooped become a period of data coverage on IBES was following bankruptcy or because the number of months of data coverage was too short. The cample consists of 68 bankrupt firms.

This process of provided on the administration of

non-bankrupt firm from the same industry (three digit 512 locate) and of approximately the same size.

Matching on industry is desirable to control for industry characteristics and conditions. Forecast uncertainty may be related to industry. Furthermore, information events may have industry-wide implications leading to industry-wide revisions in earnings forecasts.

Matching on size is desirable because size is associated with risk, probability of bankruptcy, analyst attention, and most likely, the number of sources from which consensus forecasts and summary statistics on the IBES tape are developed. Using total assets as a measure of size, 58% (42%) of bankrupt firms were larger (smaller) than their non-bankrupt matched firm. Using total sales as a measure, 50% of bankrupt firms were larger than their con-bankrupt match. Both parametric (thest) and non-parametric (wilcowon sign rank) tests revealed no significant difference in size tite between bankrupt and non-bankrupt groups, so the world to process was apparently successful.

THE PROPERTY OF THE PROPERTY O

The 68 matched pairs represent the maximum sample available for the analysis conducted. However, data for each firm was not available on ISES for each month and year of the test poriod. In addition, in some months where data was available, ISES include forecasts from only one analyst while certain measures used in the endicate (n.g. c) and and deviation of cultiple forecasts) reports for the forecasts from the conduction of cultiple forecasts) reports.

tests were conducted on sample sizes lass than 68.

Matching on fiscal year-end would perhaps be desirable ont was not possible without a great reduction in sample size. Data for each firm in a given matched pair were however taken from the same fiscal year. Within a given year there is substantial evidence that the properties of analysts forecasts change as the year-end approaches. For example forecasts tend to become more accurate as the end of a reporting year approaches. However, data in the study is analyzed in "event" time rather than "calendar" time, which minimizes any problem associated with firms having different fiscal year ends.

2.3 A Word on Notation

Consider

ESSANDE MANDEN ENERGY ENERGY DENGELS DE L'ESSANDE DES ESSANDIELLE DE L'ESSANDE PROPERTIE DE L'ESSANDE PROPERTIE DE L'ESSANDE DE L'ESSAN

Notation used in the study also refers to event time. Two events are of importance: the year in which bankruptcy is declared for the bankrupt firm and the month relative to fiscal year-end within any year. The notation used treats bankruptcy as time "zero" and zounts becoward in time such that both years and not increase as the time before bankruptcy or year-end increases. The percent is the year in which bankruptcy is declared for a bankrup firms (and the corresponding fiscal year for the corresponding fiscal year for the corresponding fiscal year one is the fiscal we immediately prior to the year in which bankruptcy is declared. Within any given fiscal year, month zero is the last month in the year is the corresponding fiscal year. December for a film with December 1) year-sends. The corresponding to the last month in the year is the last month in the year.

three month intervals corresponding to the end of quarters.

3. Properties of Analysts Earnings Forecasts

3.1 Measurement of Properties

Four properties of analysts earnings forecasts were investigated: 1. The average (mean) forecasted earnings provided by forecasters (available on IBES); 2. The accuracy in forecasts when compared to actual earnings; 3. The bias in forecasts (whether they under or over predict actual earnings); and 4. The dispersion in forecasts across multiple forecasters.

First, measures to reflect the four primary properties of interest were constructed as follows:

Mean Forecast = ME = \hat{Y}_{tm}

Forecast Error = ERR = | Ŷem - Ye

Forecast Bias = BIAS = $\hat{Y}_{tm} - Y_t$

Where:

CANADA CONTRACTOR CONT

 $Y_{\rm km}$ = Mean Forecasted EFS for year t provided at month $m_{\rm s}$

Ye = Actual reported EPS for year t

to 1 or 2 (years prior to bankruptcy)

a = 0.7, c.9 (about the prior to year end)

(Each of these measures is uncaffals). Alternative measures for created by deflating by stockprice and, where appropriate, by reported earnings. Overall findings were the same and no results using deflated measures are reported.)

Second, to reflect how the properties change within a given forecast year (intra-year changes), the difference between measures of the properties taken at two points within a year was computed. For example, the change in mean forecasted earnings (MECHG) between the forecast at year end and at months earlier in the year was determined as follows:

MECHS = MEe,o - MEem Where m=3,6 or 9

Analogous measures reflecting the intra-year change in foreignst error (ERRCHG) and in forecast dispersion (SDCHG) were developed.

(The intra-year change in forecast bias is mathematically equivarient to MECHG and thus is not considered.)

Third, to reflect how properties change across different years (inter-year trends), the difference between measures or the properties taken (at the same month) in successive were war computed. For example the trend in mean forecasted earnings (METRND) was determined as follows:

METRND = $ME_{em} \sim ME_{em,em}$ Where t = 1 or 2 Analogous measures reflacting inter-near trends in Analogous reasons (SDFAND) and forecast dispersion (SDFAND) were daysloped.

J.D. D. Est (on a of Itterest

THE PARTY OF THE PROPERTY OF THE PARTY OF TH

 failing and healthy firms? Are there systematic group differences in how the properties change within a forecast year? Are there systematic group differences in how the properties change aircs forecast year? Group means for each of the measures of interes, and non-parametric wilcoxon tests of significance of the difference in group means are presented in following tables.

3.3 Mean Forecasted Earnings

AND THE PROPERTY OF THE PROPER

Die obvious place to look for differences between failing and healthy firms is simply in the level of future earnings predicted for firms in each group. Although low earnings does not in liberary and high earnings does not insure health, one concepted expect some relationship between the level of earnings and the probability of future failure. While reported earnings may contain information relevant to distinguishing between groups, forecaster earnings are future looking and consequently have the potential or reflecting espects of firm health that have not yet been reflected in reported earnings.

Table 1 shows highly significant test results related to the level of forecasted earnings. Several findings of note: First, locking at ME, for all months within a forecast year, for both wears ories to bon septem, supplied to lower decrease of predicted for the failing firms.

Gerand, looking at MECHG, negative values indicate a decline to the level of forecast dieversing, as year end approached. There we negative 2000 for access on built flor failing and hearth. The

The second seconds seconds seconds seconds

This is not surprising. Forecasts in general could be optimistic and require downward revisions if general economic conditions were deteriorating. The fact that the measures are taken in years just prior to bankruptcy for the failing firms, coupled with the fact that bankruptcies increase in times of overall economic stagnation, is consistent with those years being periods of optimistic forecasts even for the healthy firms. Despite the declining earnings forecasts for both groups, the MECHG tests indicate significantly greater intra-year declines for failing firms.

Third, looking at METRND, it is also apparent that the failing firms exhibit a downward trend in earnings forecasts across wears, which is not exhibited by the healthy firms. The tests suggest that measures reflecting forecasted earnings, and changes in forecasted earnings both within and across years may be potentially useful in distinguishing failing from healthy firms.

T.4 Accuracy - Forecast Error

Fast investigations of the accuracy of analysts common to (see Givoly and Lakonishok [1984] for a review) have generally focused on two questions: Are analysts forecasts more accurate than forecasts from mechanical models? And how do analyst's (reseasts to ober to management surscoasts) of cults or could comparing analysts forecasts with forecasts from numerous soles of mechanical models have observed been contradictory, soles of party of analysis and the contradictory. Soles of party of analysis of the contradictory of the contradictory of the contradictory of the contradictory.

forecasts suggest in alight but insignificant adventage to a town ment. These results are not surprising. One would expect analysis to out-perform mechanical models given the wider information set on which analysts may rely. Likewise, one would not be surprised at the essentially similar performance between analysts and management given their similar information sets and the incentives for management to provide information to analysts (Ajingya and Gift [1984]). The objective here is to test for systematic differences in analyst acturacy between failing and healthy firms.

Table 2 provides test results. Forecast errors (E/R) are consistently significantly greater for failing firms on hoth years prior to bankruptcy, regardless of the month in which the toraclast This is consistent with the argument of Currentae and is made. Givoly [1982] that forecast errors reflect risk. Past research has indicated that forecast errors (tend to decline (t.e. .tc / this accoracy) as year-end approaches (e.g. Thom. Grober of 3 tobula 519841'. Increasing accuracy is evident in the present sample for inthe failuing and these terms of an acceptable of in my entermessures). This is a pacted since more and better into a firm becomes available as the period progresses. Forecast errors, however, are associated with risk and uncertainty. For the +x.lin. in the community of the complete exploration of the contribution o banking to, . One might hipothesize that approaching Lankinght result in a relatively smaller increase in forecast ac practicles representation for the second of the contract

		0/9	-1.86	30	-2.54	.011

is some 'moom or improvement' as new information arrives throughtout the year. The larger forecast errors for failing firms may allow for greater improvement and thus greater decrease in forecast errors. These two arguments suggest competing reasons for systematic group differences in intra-year changes in forecast accuracy. The later reason apparently holds in the sample. MECHG measures are significantly more negative for failing firms, indicating greater improvement in accuracy. ERRTRND measures on the other hand are larger for failing firms (in year 1) indicating increasing error and less accuracy across years. This is consistent with increasing first as bankruptcy approaches being reflected : increasing forecast error.

J.5 Forecast Bias

If forecasts are rational (Muth [1961]) they should be unbiased. While forecasters cannot be expected to predict without among, rational forecasters should in general be able to bred in without systematic error. Consistent systematic error would be able to be able to bred in consistent systematic error would be able to be able to bred in consistent systematic error would be able to be able to bred in consistent systematic error would be able to be able to bred in consistent systematic error would be able to bred in consistent systematic error would be able to bred in consistent systematic error would be able to bred in consistent systematic error would be able to bred in consistent systematic error would be able to bred in consistent systematic error would be able to bred in consistent systematic error would be able to bred in consistent systematic error would be able to bred in consistent systematic error would be able to bred in consistent systematic error would be able to bred in consistent systematic error would be able to bred in consistent systematic error would be able to bred in consistent systematic error would be able to bred in consistent systematic error would be able to bred in consistent systematic error would be able to be able to bred in consistent systematic error would be able to be able to be able to bred in consistent systematic error would be able to be

citing Barefield and Comiskey [1975] and Fried and Givoly [1982]. conclude that there is an "accumulation of evidence," though statistically insignificant, that an upward bias may be present in analysts forecasts.)

The finding of no systematic bias is consistent with rational forecasts and with the proper processing and utilization of information available in the past realizations of earnings and forecast errors. The immediate concern here is whether there is a difference in the bias of forecasts between healthy and failing firms.

Results for bias tests are in table 3. Note that group means for BIAS for both the failing and healthy firms are consistently positive, consistent with the tendency toward an upward bias (overestimation) cited by Givoly and Lakonishok. Thesets (not reported) indicate that the bias is significantly different from zero for the failing firms but not the healthy firms. From importantly the bias for failing firms is significantly greater for the vailing firms, regardless of the month within the forecast year. Measures of the trend in bias (BTRND) from year 2 to year 1 are significantly higher for failing firms, indicating increasing overestimation of earnings as bankruptcy approaches.

1.6 Forecast Dispension

STATEMENT SECRETARING SECRETARION SECRETAR

Previous research has investigated the dispersion across analysts forecasts as a measure or indication of uncertainty.

Cubierman and Divoly C19923 present a model in which the dispersion or forecasts as a measure or indication of uncertainty.

TABLE 4

dispension of the distribution of expected learnings and therefore with the cross-sectional error in forecasts. Empirical evidence supported their model; measures of dispersion were positively associated with measures of forecast error. Results from Eltan. Gruber and Gultekin [1984] also document this relationship. Cakierman and Givoly argue that the cross-sectional error in earnings is the empirical counterpart of uncertainty. Dispersion of earnings forecasts have also been found to be associated with traditional risk measures such as beta, the standard deviation of returns and earnings growth variability (Givoly and Lakonishok [1983].) The purpose here is to determine if measures of discersion differ systematically between failing and healthy firms as bankruptcy approaches. The implicit assumption is that forecast dispersion measures may reflect risk that is ultimately manifested in bankruptcy.

RESS BOSSESSO BESSESSO STATES TO THE RESSESSOR RESSESSOR FROM THE SECURITY FOR THE RESSESSOR FOR THE SECURITY FOR THE PROPERTY OF THE SECURITY FOR THE SECURITY

Given that dispersion may reflect uncertainty, one would hypothesize greater dispersion for failing firms and increasing dispersion, both within and across years, for failing firms. (Tests using alternative measures, such as the range, variance and coefficient of variation, were conducted with similar results.)

Tests for group differences in SD, reported in table 4, show significantly greater disparsion for feiling firms throughout the two years prior to bankruptcy (year 2, month 9 excepted). Observing the group means for SD within each year, there is a general bandency for dispersion to increase for failing firms and decrease for healthy. Times is the year end approaches. This is a make is a

approaches (although the SDCHG lests indicate that this group difference is not generally significant). Tests on SDTRND indicate significantly greater increase in dispersion for failing firms from year 2 to year 1. Again this is consistent with impending failure increasing uncertainty and being reflected in greater dispersion of forecasts.

4. Tests of Discrimination

4.1 Measures used

The previous results indicate that there are group differences for each of the four primary properties of earnings forecasts in years prior to bankruptcy, and group differences in how those properties change both within years and across years. The question here is whether measures of those properties and their changes can be amploited to predict future bankruptcy. For each year (1 ar prior to bankruptcy, a single measure was selected to represent eact of the pricary properties (ME, ERR, BIAS, SD), each of the intra-year changes (MECHG, ERRCHG, SDCHG) and each of the interyear trends (METRND, ERRTRND, BTRND, SDTEND); eleven variables in ictal. Measures of the primary properties are taken at lear end is also Dig. inclinates of Lintin-year trends used month $\mathbb C$ as a $x \in \mathbb R$ successive years; measures of lintra-year changes used the differcace between month O and month & measures. The selection, emphasis ole, you make instrument is a compatibulitary but it commones a soft In world the control of the control

approaches. Since measures taken at different months within a pear tend to be highly correlated for a given firm, use of measures developed at months different from those selected could be expected to lead to similar findings.

risclassified As a first step toward using forecast information to predict failure, a univariate analysis was conducted. The approach used follows Beaver (1966). The procedure is straight forward. Sample firms were rank-ordered independently on each of the measures of The rank-ordered values for a given measure were visually observed. A cutoff or threshold value of the measure was selected to divide sample observations into failing and health: Cutoff values were selected that minimized the percentage of firms misclassified. Results using measures from year t and year 2 are provided in the top part of tables 5 and 6, respect

Five items relating to errors in classification are provided under the "classification" column in the tables: The type 1 error is the percentage of failing firms misclassified as healthy. type I error is the percentage of healthy firms misclassified as $ilde{ ilde{ ilde{ ilde{I}}}$. The average error is a weighted average of the type $ilde{ ilde{ ilde{I}}}$ and type I cannons and thus depresents the overall classification of a The percentage in the Naive column is provided as a benchcompanison. It represents the fraguency o or salessification boyons from the full wing carive close. Fit to be

resilassification errors from the following harve classification cule: assign all firms to the group (failing or healthy) with the highest frequency in the sample. (This generally meant classifying all firms as healthy because data limitations were such that healthy firms outnumbered failing firms in the samples used to develop the cutoffs).

The final item in the table is a rough measure of the efficiency (EFF) of using the cutoff on a variable to classify firms when compared to using the naive approach. It is calculated as the error rate from the naive approach minus the error rate from the cutoff approach divided by the error rate from the naive approach, and thus measures the percentage of firms that were misclassified by the naive approach that were correctly classified by the cutoff approach. EFF equals zero when the naive and cutoff approach have the same overall error rate. Higher positive values of EFF indicate increasing superiority of the cutoff approach over the naive rule, with a value of one indicating no errors in classification. Negative values indicate that the cutoff approach was less successful than the naive rule.

developing the catoff value on each subsample, and using the interfrom each subsample to classify the firms in the other saluation. Findings from using this approach are unbiased. They are contained in the second set of results under the "verification" column.

Another approach to validation is to determine validity across time. The remaining column in the tables, labeled "prediction", shows the results of applying the cutoffs developed in one year prior to bankruptcy to the measures available for sample from another year.

Several broad conclusions can be drawn from the tables.

- a. The frequency of type 1 errors is consistently greater took the frequency of type 2 errors. This is unfortunate since the costs associated with type 1 errors are likely to be greater to make associated with type 2 errors. But given the approach used, such results are likely to occur if, as in reality, the frequency of healthy firms in a sample is greater than the frequency of facility firms.
- D. EFF values are generally positive, indicating a 1 univariate approach does have some ability to identify group membership. However, the superiority of using cutoff values as compared to the naive approach is frequently marginal for the law of the response.
- c. Regardless of which year the cutoffs are developed on, there is a tendency for errors to be smaller in year to him year to him year to him year to him year to have a local to the mercures have a local to the story follows forms, it is a coerties of follows or the second of the s

hone dylident as ben'huptav approaches.

d. One would like to have a measure for measures) that is is valid in that it performs well on the verification tests and b) is consistent. In that it performs well in more than one year prior to bankruptcy, i.e., performs well in the prediction tests. Overall, measure ME performs best. Average error rates for ME teri to be low and efficiency rates relatively high. The ability of a cutoff based on ME to outperform the naive approach tends to be the most consistent across the verification and prediction tests and at our the years. Regardless of the year (1 or 2) in which the cutoff walue is determined, use of ME allows for a discrimination of first in the two years prior to bankruptcy which is markedly better to see that we rule. Efficiency indicators suggest that about 33-49% of firms misclassified by the naive rule can be correctly classified taking a cutoff based on ME.

4.7 Multi ariate Indo Opproach

Ey far the hist popular abondach to development in a prediction models has been multiple discriminant analysis. These Taygren [1983] for review.) However, its use in bankruptcy studies has been criticized (e.g. hover [1977]). Moses and that [1986] a plant models in models are into their study out performs distribution of a hearing independent of their study out performs distributional models in predicting tailors. From the construction of the individual observation of the contract of the c

an index. are simple. For each of the individual measured used in the univariate tests, firms were assigned a score of 1 if they tell on the "benkruptcy" side of the cutoff. and 0 otherwise. They scores were totaled for variables that were to be included in a given index. Four different indexes were examined as follows (each included scores from the variables indicated):

- 1. Primary Variables (FR): ME, ERR, BIAS, SD
- 2. Primary & Trend Variables (PRTRND): ME.ERA.SIME.LL: METRND, ERRITAND, BIRND, SDIRND
- T. Primary & Change Variables (PRCHG): ME. ERR. Blad. ED: MECHG. ERROHG. SDCHG
- 4. All Variables (ALL): all eleven measures

Firms were rank ordered on the total score provided by the cover index and a cutoff score that minimized errors in classification was determined by viewing the ranking. Classification in a line of the four indexes are provided in the bottom part of tables 5 of a seasonable than aniation approached to the procedure was live or holdout samples in the same year and to data from a different year. The analogous results are reported under the verification and a ediction columns in tables 5 and 6. (The verification brook the religion is selecting the variables to be uncluded to the radio of indetermining the ceto-fold

5. Conclusions

Feets from the testing to their measures of more field in

measures investigated in the study were able to outpercent a war a classification rule. The most useful single measure for predicting ruture failure is mean forecasted earnings, but indexed continuing nultiple measures reflecting the properties of analysis arrangs forecasts are superior to mean forecasted earnings in calticly situations. The measures and indexes tested here are not in general superior to models using accounting data (see Calgren 1987) for a superior, however, other approaches to measuresett or variables or model construction could alter that conclusion.

There are several areas for follow research. First alternative following massures developed from earnings forecasts, measures developed from enagement earnings (orecasts could be investigated. Detond more abusinated model deviloting approaches such as logic could be approaches such as logic could be approaches for the solution of th
